

HORMONE RECEPTORS: ASSOCIATION WITH PROGNOSTIC FACTORS FOR BREAST CANCER

Receptores Hormonais: Associação com Fatores Prognósticos para Câncer de Mama

Ana Lucia Amaral Eisenberg¹, Sergio Koifman² e

Lidia Maria Magalhães Cordeiro de Rezende¹

ABSTRACT

Positivity for hormonal receptors (HR) in breast cancer patients is associated both with a better prognosis, and with variables predictive of favorable prognosis. A study was designed to assess predictors of positivity of estrogen (ER) and progesterone receptors (PR). Data from 306 patients with infiltrating ductal carcinomas who were consecutively diagnosed and treated over a period of 20 months were included. Selected variables related to patients and tumors (micro and macroscopic characteristics as well as immunohistochemically-determined tumor markers) were studied. Bivariate analysis showed that some of variables were associated ($p \leq 0.05$) with the HR positivity: age ≥ 60 years, post-menopause, age at menarche (> 11 years), tumor size (< 4.0 cm), histological grade (low), nuclear pleomorphism (low), number of mitoses (low), MIB-1 (negative) and p53 (negative). Unconditional logistic regression revealed that the following variables were independent predictive factors of positivity of ER: age ≥ 60 years ($p < 0.001$), histological grade I ($p < 0.05$), positive PR ($p < 0.001$) and negative p53 ($p < 0.05$). For PR, two models were evaluated: a) age ≥ 60 years ($p < 0.05$), age at menarche > 11 years ($p < 0.05$) and histological grades I and II ($p < 0.05$); b) histological grades I and II ($p < 0.05$) and positive ER ($p < 0.001$). In this study, only age at diagnosis, histological grade, PR and p53 were independent predictors of positivity of ER. Age at diagnosis, age at menarche and histological grade (or histological grade and ER) predicted a positive PR.

Key words breast neoplasms; hormonal receptors; carcinoma infiltrating duct; tumor markers biological; logistic regression; histological grade; nuclear pleomorphism grade.

RESUMO

Os tumores de mama positivos para receptores de estrogênio (RE) e/ou de progesterona (RP), além de apresentarem um prognóstico mais favorável, mostram associações com outras variáveis de bom prognóstico. A partir de um estudo com 306 carcinomas ductais infiltrantes de mama, foram construídos modelos preditivos para a positividade dos RE e dos RP. Foram estudadas variáveis relacionadas às pacientes e ao tumor (características macro e microscópicas e marcadores tumorais processados por imuno-histoquímica). Na análise bivariada, algumas variáveis se associaram estatisticamente com a positividade dos RE e RP, porém, na regressão logística não condicional somente as seguintes variáveis foram fatores preditivos independentes: idade da paciente (RE e RP), idade da menarca (RP), grau histológico (RE e RP), RP (RE) e p53 (RE). De acordo com os resultados deste estudo as variáveis idade da paciente ao diagnóstico, grau histológico, RP e p53 foram fatores preditivos para a positividade dos RE, enquanto que a idade da paciente, a idade da menarca e o grau histológico o foram para os RP.

Palavras-chave: neoplasias mamárias; carcinoma de ductos infiltrante; grau histológico; grau nuclear ou pleomorfismo nuclear; receptores hormonais; marcadores biológicos de tumor; regressão logística.

INTRODUÇÃO

According to Rosen (1997), hormonal receptors (HR) are proteins that bind to circulating hormones, mediating their cellular effects. The most extensively studied receptors in breast cancer are estrogen receptors (ER) and progesterone receptors (PR)¹.

According to Patino *et al.* (1988), some two-thirds of breast cancers are HR-positive², but this figure varies from one author to another. For example, while Zeng & Xu (1991)³ found positive rates of 72% for ER and 54% for PR, Elliott *et al.* (1994) found 60% and 44%, respectively⁴.

Most authors show a positive association between the presence of a HR (ER and/or PR) and a favorable prognosis, for both disease-free and overall survival^{2,5-13}.

The literature also includes several studies showing associations between the presence of a HR (ER and/or PR) and other indicators of good prognosis: white patients⁷; postmenopausal patients^{1,5,7,11,14}; small tumor size^{13,15}; low histological grade^{6,13-15}; low nuclear grade^{6,14,15}; and low mitotic activity¹⁴.

The findings are conflicting with regard to tumor markers. While some studies show associations between positive HR (ER and/or PR) and absence of markers¹⁶⁻¹⁹, others have failed to find such associations²⁰⁻²³.

All these findings have important treatment implications, since the value of HR (ER and PR) studies in predicting response to hormonal treatment for advanced breast cancer is well-founded: positive response rate is 77% for ER/PR-positive tumors; 46% for ER-negative PR-positive tumors; 27% for ER-positive PR-negative tumors; and 11% for ER/PR-negative tumors²⁴.

Considering the relative scarcity of research in Brazil on HR patterns in women with breast cancer, this study focused on the construction of predictive models for HR in hospitalized patients with breast cancer and their association with selected variables.

METHODOLOGY AND DATA SOURCES

All malignant breast tumors (incident cases) submitted to surgery with lymph node dissection by the Mastology Service of the Cancer Hospital/Brazilian National Cancer Institute (HC/INCA), the largest public reference hospital for cancer in the city of Rio de Janeiro, Brazil, from January 1, 1995, through August 31, 1996, were obtained. A respective slide review was carried out twice at the Anatomic-Pathology Service by two pathologists (authors ALAE and LMMCR)

without consulting any other patient data.

Following a review of all available slides, with a total of 398 tumors diagnosed previously as malignant, 306 were reclassified as infiltrating ductal carcinoma (IDC), and only this histological type was analyzed in this study, considering both its higher prevalence and worse prognosis²⁵⁻²⁷.

Macroscopic and microscopic study characteristics were the following: type of surgical specimen (quadrantectomy; segmentectomy; simple mastectomy; Patey mastectomy; radical mastectomy; other); tumor size (largest diameter in centimeters); formation of tubules ($\geq 75\%$; 10 to 74%; $< 10\%$); nuclear pleomorphism (mild; moderate; intense); number of mitoses per ten high-power fields, hpf ($< 10/\text{hpf}$; 11 to 20/hpf; $\geq 20/\text{hpf}$); histological grade as proposed by Bloom & Richardson (1957)²⁸ and later modified by Elston & Ellis (1991)²⁹ (well-differentiated or grade I; moderately differentiated or grade II; poorly differentiated or grade III); vascular and/or lymphatic invasion; multicentricity; skin and/or nipple involvement; total number of lymph nodes examined; total number of lymph nodes involved by neoplasia; presence of perinodal fat infiltration; and surgical limits condition.

Recovery of antigen in the immunohistochemical preparations was performed by moist heat (pressure cooker). Method of detection was the peroxidase-antiperoxidase reaction (PAP), based on Sternberger *et al.* (1970)³⁰ and adapted by Santos *et al.* (1995)³¹. The preparations were also analyzed at the same time by the two above-mentioned pathologists. Assessment of stained neoplastic cell distribution was performed, and only those moderately or intensely stained were considered positive; weakly stained cells were considered negative. The cut-off used to separate positive and negative stains was 10% of stained cells (this criterion is used by various authors in the specialized literature³²⁻³⁵). Other cut-off points used to quantify cell staining were: (+) 10 to 25%; (++) 25 to 75%; (+++) $> 75\%$. The immunoreactivity was localized in the nucleus for ER, PR, MIB-1, PCNA, and p53, in the cell membrane for c-erbB-2, and in intracytoplasmic granules for cathepsin-D.

Data obtained from patient files were the

following: age at first diagnosis; time between initial symptoms and first consultation at the HC/INCA; age at menarche; age at menopause for patients having reached menopause naturally or by surgery; number of pregnancies, number of births and spontaneous or induced abortions; age at first at-term delivery for patients having given childbirth; family history of breast cancer; degree of affinity for family history of breast cancer (mother; daughter; sister; grandmother; aunt; cousin; other); family history of other types of cancer; anatomical site of family cancer (ovary; endometrium; colon; other).

Databank organization was performed with EPI-INFO software version 6.04 (U.S. Department of Health and Human Services and Public Health Service and Centers for Disease Control, USA). Bivariate analysis included crude odds ratios (OR) with 95% confidence intervals (CI) aimed to estimate the degree of association between the study variables and the HRs; chi-square test (χ^2) of linear trend for ordinal variables; chi-square test of independence (χ^2) to evaluate null hypothesis of the observed associations; Mantel-Haenszel OR (OR_{MH}) and 95% confidence intervals, following stratification of selected variables. Further, unconditional logistic regression was developed for the construction of parsimonious models in the determination of hormonal receptors (ER and PR) as outcome in patients with breast IDC, using EGRET software (Epidemiological Graphics, Estimation, and Testing, version 0.26.6, 1985-1991, SERC & CYTEL).

Independent variables tested in the multivariate analysis (logistic regression) were chosen following the previous stages (bivariate and stratified analyses) as well as biological criteria evaluated by the authors. Potential confounders and variables showing significant p-values (at 5%) for presence of interaction were selected for logistic regression, as well as variables of biological interest.

RESULTS

In this study the positivity for ER and PR was, respectively, 55,2% and 41,8%.

The main associations observed between the selected variables and ER and PR are

presented, respectively, in Tables 1 and 2. Firstly, a gradual and linear increase of OR between ER-positivity and age was observed ($p < 0.0001$) in Table 1, where the lower the level of ER positivity, the higher the observed OR. The same is shown in Table 2 for PR.

A statistically significant positive association was also found between ER and menopausal status (pre- vs post-menopause), [OR = 2.39 (95% CI = 1.38-4.16); $p = 0.0008$]. The association observed between PR and this same variable was small and not statistically significant ($p = 0.37$).

Using patient's age as the main predictive factor for the study outcomes, ER and PR, [ER vs patient's age: OR_{crude} = 2.78 (95% CI = 1.67-4.64); PR vs patient's age: OR_{crude} = 1.75 (95% CI = 1.06-2.87)], stratification was performed for associations between ER and patient's age (Table 3) and PR and patient's age (Table 4) with the other variables described above.

Candidate variables for inclusion in the model were those which the stratified analysis suggested to be potential confounders and/or interaction variables (menarche, tumor size, histological grade, number of mitoses, PR, and p53 for ER outcome; and menarche, ER, and number of mitoses for PR outcome). For PR outcome, histological grade was also included, since according to the literature, high histological grade tumors tend to be PR-negative^{6,13,14}.

Since interaction between age and number of mitoses is biologically implausible, we opted not to include an interaction term between these variables.

The test models contained only the following variables: (a) for the ER outcome: patient's age, tumor size, number of mitoses, histological grade, menarche, PR (negative vs positive), p53 (positive vs negative); (b) for the PR outcome: patient's age, menarche, number of mitoses, histological grade, and ER (negative vs positive).

For modeling ER outcome, after several attempts including and excluding variables according to their isolated and model's statistical significance, we opted for that containing the following variables: PR (negative vs positive), patient's age (< 60 years vs ≥ 60 years), p53 (positive vs negative), and histological grade (I vs II vs III) ($p <$

0.001) (Chart 1.1).

After similar procedures for modeling the PR outcome, we opted for two models that were considered acceptable: a) one containing the variables histological grade (I vs II vs III), patient's age (< 60 years vs ≥ 60 years), and menarche (≤ 11 years vs > 11 years) (p -value < 0.001); the variable ER (negative vs positive) did not reach statistical significance in this model (Chart 1.2.1); b) and a smaller model, containing only the variables ER (negative vs positive) and histological grade (I vs II vs III) (p -value < 0.001), which did not accept any other variable with a significant p -value (Chart 1.2.2).

DISCUSSION

According to the literature, both ER and PR positivity are highly associated with patient's age at diagnosis: tumor HR-positivity increases significantly with age, that is, positivity is greater in women 60 aged years or older, as well as in post-menopause¹. In this study, both ER and PR were significantly associated ($p < 0.05$) with patient's age (< 60 years vs ≥ 60 years). When the association was studied between different levels of positivity for HR (+++ vs ++ vs + vs negative) and patient's age (< 60 years vs ≥ 60 years), we observed a chi-square with a high linear trend and significant p -value ($p < 0.01$), for both ER and PR. Estrogen receptors was also significantly associated with menopausal status ($p < 0.001$), but PR was not.

The current study also found a statistically significant association between PR (negative) and early menarche (≤ 11 years) ($p < 0.05$), a result which disagreed with Rosen (1997)¹, who failed to find this association. The association found for this study between ER (negative) and early menarche was statistically borderline ($p = 0.09$).

In agreement with the literature, our bivariate analysis showed statistically significant associations between ER- and PR-positive tumors and other good prognostic indicators, such as: tumor size shorter than 4.0 cm ($p < 0.005$)¹³; low histological grade ($p = 0.01$); low nuclear grade ($p < 0.01$)^{1,6,13,14}; and reduced mitotic activity ($p < 0.001$)¹⁴.

χ^2 trend: χ^2 of linear trend

al (1996)¹³ showed that the presence of hormonal receptors (ER and PR) were not associated with nodal status and so did we in our study.

According to Rosen (1997)¹, most PR-positive tumors are also positive for ER, and our study found an OR of 22.80 between both (95% CI = 11.10-48.00; $p < 0.0001$).

In disagreement with the literature, which mentions strong and statistically significant associations between hormonal receptors and *c-erbB-2*^{18,19,36-38}, our study failed to find such associations.

Querzoli *et al.* (1996)³⁹, Seshadri *et al.* (1996)⁴⁰, and Sundlad *et al.* (1996)⁴¹ found inverse associations between MIB-1 and hormone receptors (ER and PR), while Pinder *et al.* (1995) found no such association (MIB-1 and ER)⁴². In the current study, only ER was inversely and significantly associated with MIB-1 ($p = 0.05$); our study also found no significant association between PCNA and HR, unlike Siitonen *et al.* (1993)⁴³ and Gasparini *et al.* (1992)⁴⁴.

In disagreement with Henry *et al.* (1990)⁴⁵ and Eng Tan *et al.* (1994)⁴⁶, we found no association between increased expression of cathepsin-D and estrogen receptors.

Most studies, including ours, found statistically significant inverse associations between ER and PR and p53 ($p < 0.001$). Barbareschi (1996)⁴⁷, in a bibliographical review, found associations between p53 and ER in 8 out of 11 studies and between p53 and PR in 7 out of 9, where such associations had been investigated. A literature review showed an association between p53 and ER in several studies⁴⁸⁻⁵⁶ and no such association in only one⁵⁷. Association between p53 and PR was also present in some studies^{49,52,55,57,58}.

In summary, the results of bivariate analysis in the current investigation agree with the literature as to the association between positive HR and the variables patient's age (60 years or over), menopausal status (post-menopause), tumor size (smaller than 4.0cm), histological grade (low), nuclear pleomorphism (low), mitotic activity (low), MIB-1 (negative), and p53 (negative), while they disagree in relation to the variables age at menarche, *c-erbB-2*, cathepsin-D, and PCNA.

Using a multivariate approach, only patient's age, histological grade, PR, and p53

were significantly associated with ER (Chart 1.1). For the PR outcome, independent factors included patient's age, age at menarche, and histological grade in one model (Chart 1.2.1), and only histological grade and ER in another (Chart 1.2.2).

As mentioned above, study of hormonal receptors is important for predicting both breast cancer prognosis and response to hormone therapy. Although it was not this study's aim (since patient follow-up was not carried out), one can suggest that the group of patients with ER- and PR-positive tumors probably has a better prognosis, since positivity for both (ER and PR) was associated with variables also related to a better prognosis.

CONCLUSIONS

According to this study, the variables patient's age, histological grade, PR-positivity and p53 were significantly associated with presence of ER, while the variables patient's age, age at menarche, and histological grade (or histological grade and ER-positivity) were significantly associated with the presence of PR in women with infiltrating ductal carcinoma of the breast.
